spFRET Using Alternating Excitation and FCS Reveals Progressive DNA Unwrapping in Nucleosomes

W. J. A. Koopmans, R. Buning, T. Schmidt, and J. van Noort*
Physics of Life Sciences, Leiden University, Leiden, The Netherlands

ABSTRACT Accessibility to DNA wrapped in nucleosomes is essential for nuclear processes such as DNA transcription. Large conformational changes in nucleosome structure are required to facilitate protein binding to target sites within nucleosomal DNA. Transient unwrapping of DNA from nucleosome ends can provide an intrinsic exposure of wrapped DNA, allowing proteins to bind DNA that would otherwise be occluded in the nucleosome. The molecular details underlying these mechanisms remain to be resolved. Here we show how DNA unwrapping occurs progressively from both nucleosome ends. We performed single-pair fluorescence resonance energy transfer (spFRET) spectroscopy with alternating laser excitation (ALEX) on nucleosomes either in free solution or confined in a gel after PAGE separation. We combined ALEX-spFRET with a correlation analysis on selected bursts of fluorescence, to resolve a variety of unwrapped nucleosome conformations. The experiments reveal that nucleosomes are unwrapped with an equilibrium constant of ~0.2–0.6 at nucleosome ends and ~0.1 at a location 27 basepairs inside the nucleosome, but still remain stably associated. Our findings, obtained using a powerful combination of single-molecule fluorescence techniques and gel electrophoresis, emphasize the delicate interplay between DNA accessibility and condensation in chromatin.

INTRODUCTION DNA-protein complexes are transient by nature. To understand the reaction mechanisms that control DNA metabolism it is important to relate the association and dissociation kinetics of these complexes to the conformational changes that are associated with DNA binding. All transactions involving eukaryotic DNA occur in the context of the nucleosome, the ubiquitous DNA-protein complex that forms the fundamental unit of chromatin organization. A nucleosome core particle consists of 50 nm of DNA wrapped in nearly two turns around a histone-octamer core (1). Since nucleosomes sterically hinder enzymes that bind the nucleosomal DNA, they play an important role in gene regulation (2). Large conformational changes in nucleosome structure are required to accommodate enzymatic processes such as transcription, replication, and repair. A variety of mechanisms that promote accessibility to nucleosomal DNA has been identified (3,4), such as nucleosome repositioning, transient DNA unwrapping, or breathing, and exchange of histone dimers between nucleosomes. However, the molecular mechanisms underlying these processes remain to be resolved.

Fluorescence resonance energy transfer (FRET) is ideally suited to studying nucleosome structure and dynamics, since it is sensitive to conformational changes of 2–10 nm (5). Li and Widom used ensemble FRET experiments to demonstrate that under physiological conditions the end of nucleosomal DNA transiently unwraps and rewraps from the histone core with an equilibrium constant $K_{eq}$ of 0.02–0.1 (6). The dynamic opening and closing of the nucleosome ends is termed DNA breathing. With additional fluorescence correlation spectroscopy (FCS) and stopped-flow FRET experiments, Li et al. measured the unwrapping and rewrapping rates of the DNA breathing process (7). Because of the ensemble nature of their experiments, Li et al. could not resolve whether DNA unwraps in a single step as assumed in their model, or through multiple intermediate states, as speculated by Anderson and Widom (8).

On the single-molecule level, single-pair FRET (spFRET) has the power to probe the conformational distribution and dynamics of an ensemble of molecules, and other heterogeneities with unprecedented detail (9). In recent years, spFRET experiments provided valuable information on nucleosome destabilization and disassembly, and partially resolved structural heterogeneity in the nucleosome (10–14). However, these studies used single-wavelength excitation, and therefore FRET populations attributed to dissociated nucleosomes could not be discriminated from incompletely labeled donor-only or free DNA molecules, which display identical FRET. In addition, it remained unclear whether the DNA unwraps symmetrically from both nucleosome ends and whether intermediate states exist in this process. Finally, it is not straightforward how to relate the irreversible nucleosome disassembly studied in the latter experiments to the reversible nucleosome breathing kinetics observed by Li and Widom (6). Therefore, a comprehensive study of DNA dynamics in nucleosomes should both discriminate substoichiometric labeling and nucleosome disassembly.

Many of the uncertainties in the analysis described in the previous paragraph are resolved by applying alternating laser excitation (ALEX) (15). ALEX complements the applicability of spFRET by simultaneously reporting on fluorophore stoichiometry ($S$) and FRET efficiency ($E$) of the molecule of...
interest. This additional information is obtained by rapidly alternating donor and acceptor excitation. ALEX also allows the determination of correction factors for the detection efficiencies and quantum yields of donor and acceptor needed for accurate FRET measurements (16). Thus, using ALEX it is possible to further disentangle the heterogeneity that is inherent in nucleosome studies.

In previous studies, we observed and quantified DNA breathing dynamics on individual immobilized nucleosomes imaged with wide-field TIRF microscopy (17,18). We employed ALEX to separate photobleaching and photobleaching artifacts from true conformational changes, and obtained unwrapping and rewrapping rates similar to Li et al. (7). Despite careful optimization of sample immobilization and surface passivation, we found that nucleosome immobilization affected the conformational distribution and disrupted a large fraction of the nucleosomes (18).

Here, we prevent immobilization artifacts by measuring ALEX-spFRET on free, diffusing nucleosomes using confocal microscopy. Because the observation time is limited to the diffusion time of a nucleosome in the confocal volume, it is necessary to acquire statistics over a large number of different molecules. This inevitably results in mixing differently wrapped DNA molecules, despite ALEX selection. To separate properly folded nucleosomes from substoichiometric histone-DNA assemblies as well as increase the diffusion time, allowing for longer observation time and better statistics of each molecule, we observed nucleosomes in a poly-acrylamide gel after electrophoresis. Using this strategy, we compared equilibrium constants of DNA breathing at different locations within the nucleosome, and studied a variety of nucleosome conformations with a correlation analysis on selected bursts.

MATERIALS AND METHODS

Preparation of DNA and nucleosomes

Using salt dialysis, we reconstituted nucleosomes on three DNA templates with a Cy3B-ATTO647N FRET pair (Förster radius R0 = 5.5 nm) at either of the nucleosome extremes (labels at position X, or at position Z), and a position-27 basepair (bp) from one nucleosome end (labels at position Y), as shown in Fig. 1 a. Unless stated otherwise, experiments in this work were performed with nucleosomes labeled at position Y, which we refer to as internally labeled in this work. Details on nucleosome reconstitution and sample preparation are given in the Supporting Material.

Single molecule fluorescence microscopy

Single nucleosomes were imaged with a home-built confocal microscope equipped with a 60× water-immersion microscope objective (NA = 1.2, Olympus, Zoeterwoude, The Netherlands), as schematically depicted in Fig. 1 b. A 515-nm diode-pumped, solid-state laser (Co bolt, Solna, Sweden) and a 636-nm diode laser (Power Technology, Little Rock, AR) were used as excitation sources. The lasers were alternated at 20 kHz by analog modulation, either directly (636 nm) or with an AOM (515 nm; Isomet, Springfield, VA). The beams were spatially filtered with a single-mode fiber, and focused 25 µm above the glass-buffer interface by the objective. The confocal volumes were 1.5 ΦL and 2.0 ΦL for 515-nm and 636-nm excitation, respectively, as determined from FCS calibration experiments on 100-nm tetraspeck fluorescent beads (Invitrogen, Breda, The Netherlands). The excitation power was 80 µW for 515-nm excitation, and 50 µW for 636-nm excitation. The collected fluorescence was spatially filtered with a 50-µm pinhole in the image plane, and was split into a donor and an acceptor channel by a dichroic mirror (640dxcx, Chroma, Rockingham, VT). The fluorescence was filtered with emission filters (hq570/100m for the donor channel, hq700/75m for the acceptor channel; Chroma) to minimize crosstalk, and was imaged on the active area of single photon avalanche photodiodes (model No. SPCM AQR-14; Perkin-Elmer, Waltham, MA). The photodiodes were read out with a TimeHarp 200-photon counting board (Picoquant, Berlin, Germany). In a typical experiment, data was collected for 10 min and 1000–5000 bursts of fluorescence were detected.

Data analysis

Photon arrival times in the donor and acceptor channel were sorted according to excitation period, resulting in four photon streams: 

\[ I_{515}^D, \text{ donor emission during green excitation} \]
\[ I_{515}^A, \text{ acceptor emission during green excitation} \]
\[ I_{636}^D, \text{ donor emission during red excitation} \]
\[ I_{636}^A, \text{ acceptor emission during red excitation} \]

Example data is shown in Fig. 1 c. The total fluorescence emission was analyzed with a burst detection scheme (19). A burst was detected if a minimum of 100 photons arrived subsequently, with a maximum interphoton time of 100 µs. For each burst, we calculated the apparent FRET efficiency E (also known as proximity ratio),

\[ E = \frac{N_{515}^A}{N_{515}^A + \gamma N_{515}^D}, \]

and the apparent label stoichiometry S,

\[ S = \frac{N_{515}^A}{N_{515}^A + \gamma N_{515}^D + N_{636}^A}, \]

where \( N_{515}^D, N_{515}^A, \) and \( N_{636}^A \) are number of photons in the burst from the different photon streams, and \( \gamma = \Phi_A / \Phi_D \) is a parameter to correct for photophysical properties of the dyes. \( \Phi_A \) and \( \Phi_D \) are donor and acceptor quantum yield, and \( \eta_A \) and \( \eta_D \) are acceptor and donor detector efficiency, respectively. Since we only compared relative changes, \( \gamma \) was set to unity. The excitation powers were chosen such that \( N_{515}^A + \gamma N_{515}^D = N_{636}^A \) for doubly labeled molecules, resulting in S ~0.5. E and S were not corrected for donor crosstalk to the acceptor channel (11%) and direct excitation of the acceptor fluorophore (<2%). The relative size of a certain population was determined from the number of bursts matching defined E, S-thresholds. The equilibrium constant \( K_{eq} \) for DNA unwrapping was calculated as

\[ K_{eq} = \frac{\text{unwrapped fraction}}{\text{wrapped fraction}}. \]

Correlation curves \( G_{1,2}(t) \),

\[ G_{1,2}(t) = \frac{(I_1(t)I_2(t + \tau))}{(I_1(t)I_2(t))} - 1, \]

where \( I_1(t), I_2(t) \) are the photon streams of interest, and \( \tau \) is the lag time, were computed with the multi-tau algorithm described by Wahl et al. (20). The correlation curves were smoothed by averaging out the periodic contribution that comes from alternating excitation, and were corrected for afterpulsing as described (21). Correlation curves were constructed from photons during 515-nm excitation, selected from bursts matching defined E, S criteria. Although in principle any auto- or cross correlation (e.g., \( I_1 = I_2 = I_{515}^A \) or \( I_1 = I_{515}^A, I_2 = I_{636}^A \)) curve can be computed from the selected photons,
we used a particular autocorrelation function \( I_1 = I_2 = I_{D} + I_{A} \). This ensures that bursts are weighted based on their intensity and not on their FRET efficiency, facilitating a comparison of the correlation of different \( E \)-species.

**RESULTS**

**ALEX-spFRET resolves nucleosome sample heterogeneity**

We characterized the label stoichiometry and FRET efficiency of different populations in the nucleosome sample, and we performed reference experiments described in Fig. S1 and Table S1 in the Supporting Material to determine appropriate \( E \), \( S \)-thresholds between the different species. The 2D \( E \), \( S \)-histogram obtained from reconstituted nucleosomes labeled at position Y is shown in Fig. 2a. We observed a distinct, dominant population of doubly labeled and fully wrapped nucleosomes \((E > 0.25, S \sim 0.5, 78\%)\), with \( E = 0.63 \pm 0.22 \), and \( S = 0.45 \pm 0.17 \). Three other populations could be clearly resolved: doubly labeled unreconstituted DNA or unwrapped nucleosomes \((E < 0.25, S \sim 0.5, 8\%)\), and photobleached or partially labeled D-only \((S > 0.8, 8\%)\) and A-only \((S < 0.2, 6\%)\) populations. These single-molecule characteristics agree well with results obtained from separate bulk experiments (data not shown): using UV-VIS absorption spectroscopy, bulk fluorescence spectra, and PAGE, we deduced that the sample consisted of \(-80\%\) doubly labeled reconstituted nucleosomes with \( E = 0.75, \sim 8\%\) doubly labeled unreconstituted DNA, and incompletely labeled species \((-5\%\) for D-only or A-only). These results demonstrate a powerful advantage of combining spFRET with ALEX: a single experiment is sufficient to resolve the heterogeneity in the sample.

**ALEX selection resolves DNA breathing in nucleosomes**

In the FRET histogram constructed from all detected bursts (similar to the case of single-wavelength excitation), 16\% of the bursts falls in the \( E < 0.25 \) (low FRET) population, as shown in Fig. 2b. When only bursts are selected that contain both donor and acceptor labels, 9\% fall in this population that we can attribute to free DNA or unwrapped nucleosomes present in the sample.

This D-only correction enabled us to characterize and compare nucleosome reconstitutions at different label positions X, Y, and Z within their one-dimensional \( E \)-histograms, unaffected by bleaching and labeling artifacts, which amounts to 40\% of the low FRET population. We compared the resulting selected FRET histograms shown in Fig. 2c. The results are summarized in Table 1. For each reconstituted nucleosome (X, Y, and Z), the size of the low FRET population agreed well with the observed fraction of unreconstituted free DNA in PAGE experiments. Each wrapped nucleosome population showed a clear peak, with slightly different FRET efficiencies that reflect the different label attachment positions for the FRET pairs on the different DNA templates. Importantly, each distribution showed a pronounced tail extending from the peak toward intermediate FRET values. The histogram could not be fitted with a sum of two Gaussian distributions, indicating the presence of a third population of considerable size. These intermediate FRET values cannot be explained by the simultaneous transit of multiple species through the detection volume, since the concentration is low enough (100–200 pM) that the presence of more than a single molecule in the spot is highly improbable. Control measurements at 20 pM concentration showed
the tails in the FRET distribution to molecules in which spontaneous unwrapping or rewrapping of DNA occurred during their transit through the excitation volume. The observed intermediate FRET value corresponds to ~10 bp unwrapped DNA from nucleosomes X and Z, and ~35 bp from nucleosome Y. The smaller fraction in Y suggests that the first ~10–35 bp of the nucleosomal DNA progressively unwrap, starting from either end. It must be noted that the amount of unwrapped DNA mentioned here is a rough estimate, given the many assumptions needed to convert a FRET efficiency to a distance (e.g., freely rotating dyes, $\gamma = 1$, the conformation of the unwrapped DNA). To avoid this complexity, we used different label positions to monitor the unwrapping of nucleosomal DNA.

The size of the distribution allowed us to determine the equilibrium constant for DNA unwrapping. The equilibrium constants we observed were $K_{eq} = 0.19–0.37$ for end-labeled nucleosomes Z and X, and $K_{eq} = 0.07$ for internally labeled nucleosomes Y. The value of the equilibrium constant was only marginally dependent on the thresholds between the different populations, or on the thresholds used for burst detection: the number of bursts close to the thresholds $E$, $S$-values was small, and the relative size of the populations only changed a few percent when using different burst detection criteria (50 instead of 100 photons per burst, or 150 instead of 100 $\mu$s interphoton time).

**Monovalent salt promotes DNA unwrapping and nucleosome disassembly**

Although the low FRET population agrees well with the fraction of unreconstituted DNA, it may also indicate dissociation of the nucleosomes in the sample, as reported before (10). Kelbauskas et al. (13) reported that nucleosomes are less stable at physiological conditions that contain >100 mM NaCl than at the low salt concentrations used in many studies of nucleosome dynamics (7,13). To follow the structural integrity of the nucleosomes, we analyzed $E$, $S$-populations for different salt concentrations in time. We quantified the number of bursts in each population for 30 s bins and compared the relative size of each fraction as a function of time. The fraction of intact nucleosomes was monitored by evaluating the ratio of the number of $E > 0.25$ to all doubly labeled molecules, as shown in Fig. 3.

In 10 mM Tris.HCl, the fraction of intact nucleosomes was constant over time, and was equal to the reconstitution yield as determined with PAGE (90%). In contrast, at 50 and 100 mM NaCl (both + 10 mM Tris.HCl), we observed pronounced nucleosome disassembly: the fraction of intact nucleosomes decreased exponentially with a decay time of $200 \pm 30$ s after the addition of NaCl. At 100 mM NaCl, only 10% of the nucleosomes remained folded, whereas 30% was retained in 50 mM NaCl. The disassembly process was irreversible upon subsequent lowering of the salt concentration. A comparison of the FRET distributions for 0 mM and 50–100 mM NaCl was not straightforward,
because of this instability. The fraction of bursts with intermediate $E$ compared to those with high $E$ was on average higher (15%) at 50–100 mM than at 0 mM NaCl (7%), indicating that breathing dynamics was promoted at higher salt conditions. The fraction of doubly labeled species did not change over time for all salt concentrations, as shown in Fig. 3 (inset). This indicates that photobleached species did not accumulate near the detection volume, but were continuously redistributed by diffusion.

In summary, 50–100 mM monovalent salt promotes both reversible nucleosome breathing kinetics and irreversible nucleosome disassembly processes at low nucleosome concentration.

Fluorescence correlation analysis of selected nucleosome populations shows unwrapping at low FRET

By performing FCS, ALEX-spFRET allowed us to monitor the conformation of nucleosomes. FCS was applied to selected bursts to determine the diffusion time, which is directly related to the hydrodynamic radius of the nucleosomes in the selected population. We first mapped out the composition of the sample with ALEX. To characterize the hydrodynamic radius of a population matching defined criteria in $E$ and $S$, we performed FCS on doubly labeled bursts in a defined $E$-range. We calculated the autocorrelation curve $G(\tau)$ from all photons from both detection channels during green excitation, and separated three populations: $E > 0.25$ (all nucleosomes), $E < 0.25$ (free DNA or unwrapped nucleosomes), and $0.25 < E < 0.4$ (partially unwrapped nucleosomes), shown in Fig. 4.

The individual correlation curves showed a qualitatively similar decay as FCS diffusion curves reported in Hess et al. (22) that were not composed of selected $E$, $S$-bursts. In the limit of small correlation times $\tau$, $G$ was constant with an amplitude that was inversely related to the number of bursts (inset in Fig. 4). For larger lag times, $G$ decreased at $\tau = 1$ ms toward its final value $G = 0$. We determined the time-lag at half-amplitude ($\tau_1$) as the characteristic diffusion time from an FCS curve from selected bursts. Uncertainties were estimated from the change in $\tau_1$ corresponding to a change of one standard deviation in the initial amplitude of the correlation curve. The standard deviation in the amplitude was calculated using a bootstrap method, i.e., by dividing one measurement in smaller data packages analogous to Wohland et al. (23). The characteristic times were $\tau_1 = 1.2 \pm 0.1$ ms, $\tau_2 = 1.3 \pm 0.2$ ms, and $\tau_3 = 1.4 \pm 0.3$ ms for $E > 0.25$, $E < 0.25$, and $0.25 < E < 0.4$, respectively. The obtained values were the same within the statistical uncertainty, and hence the three populations were indistinguishable based on diffusion. Control measurements on a DNA template sample yielded $\tau_2 = 0.84 \pm 0.04$ ms, significantly shorter than any of the populations in the nucleosome sample. This shows that the $E < 0.25$ fraction in the nucleosome sample not only contains unreconstituted DNA, but also a significant amount of unwrapped nucleosomes with larger hydrodynamic radius.

The correlation curves of the nucleosome species did not follow a simple diffusion model typically fitted to FCS curves. We further noted that the selection process results in reduced data-sets that produce a smaller signal/noise ratio. The benefits of selecting specific species in a heterogeneous sample may, in certain applications, outweigh the reduced
signal/noise ratio associated with the combination of ALEX-spFRET-FCS. In summary, using FCS on selected populations, we deduced that the low FRET population contains a significant amount of unwrapped nucleosomes, apart from the unreconstituted DNA.

**Gel-separated nucleosomes are transiently unwrapped in a progressive way from both nucleosome ends**

To better resolve difference in nucleosome conformation, we used native PAGE to separate nucleosomes from DNA. Nucleosomes confined in a gel are expected to diffuse slower, resulting in a longer observation time, better photon statistics, and enhanced sensitivity to molecular conformation. An additional advantage of this approach is that virtual unwrapping is supplemented by sorting based on gel separation (24). This results in a well-defined nucleosome band, one not contaminated with free, unreconstituted DNA and nucleosome aggregates (two species that cannot be separated based on $S$ alone).

Low resolution fluorescence images of the gel are shown in Fig. 5, a–d (left panels). All lanes with the nucleosome reconstructions showed a sharp band of nucleosomes which migrated slower through the gel than the free DNA band. The ratio of nucleosomes to free DNA was 8:1 for the reconstitution at label position X, and 9:1 for the reconstructions at label positions Y and Z. The nucleosomes migrated in a sharp band, indicating that dilution-driven dissociation was not occurring during gel electrophoresis (~3 h), despite the elevated ionic strength of 40 mM in the gel. Trace amounts of fluorescence were detected outside these two bands, indicating that aggregation or formation of nonnucleosomal particles was small, and that these were successfully separated.

The fluorescence images allow for a quantitative measurement of the FRET efficiency of purified nucleosomes. However, transient nucleosome conformations cannot be resolved in these images. To detect these, we applied ALEX-spFRET experiments in excised gel bands of interest. The corresponding two-dimensional $E$, $S$ histograms are shown in the middle panels in Fig. 5, a–d. We observed a clear high FRET population in all nucleosome bands, with the same characteristic $E$ and $S$ values as those observed in free solution. Surprisingly, in all nucleosome bands we observed a rather large fraction of bursts with $S = 0.5$, $E < 0.25$, amounting to 38% for the end-labeled nucleosomes X and Z, and 10% for internally labeled nucleosome Y after correction for D-only species (Fig. 6 and Table 2). This fraction could not originate from free DNA and substoichiometric histone-DNA complexes, since these result in different bands in the gel. Even though the ionic strength of the buffer was 40 mM, we did not observe irreversible nucleosome disassembly during the experiment (10 min per gel band, ~1 h in total) in the time evolution of the $E$, $S$-histograms, in contrast to similar experiments in free solution. Therefore, this fraction probably reflects the nucleosomes that temporarily lose FRET by transient unwrapping. The unwrapped fractions had the same size for nucleosomes X and Z, indicating that DNA unwrapping is symmetric from both ends. Since also a considerably smaller unwrapped fraction was observed in internally labeled nucleosomes Y, we conclude that DNA unwrapping occurs progressively with a lower probability as the DNA is located further in the nucleosome. We again observed a significant fraction with intermediate FRET values (20% for X and Z, 10% for Y), that we assigned to either partially unwrapped nucleosomes, or transient unwrapping and rewrapping events during the diffusion through the confocal excitation volume.

In all gel experiments, A-only and D-only populations (12% and 20%, respectively) were more pronounced than in free solution (8% and 10%, respectively). Since nucleosomes diffuse slower in the gel, the attached FRET pair is longer exposed to the excitation light, increasing the probability that either fluorophore bleaches. ALEX allows a label stoichiometry-based sorting, and hence the presence of such bleached species did not interfere with the detection of correctly labeled low FRET species.

To gain more insight into the underlying molecular conformations, we analyzed the diffusion characteristics of the various fractions ($E > 0.25$ and $E < 0.25$) with an FCS analysis on selected bursts. The results are shown in Fig. 5 (right panels), and summarized in Table 2. The correlation times for nucleosomes were approximately three-times longer in gel than in free solution, reflecting a slower diffusion process. Furthermore, the bursts in the nucleosomes bands showed considerably longer correlation times, showing that gel-based FCS has a larger resolving power than solution-based FCS.

For all nucleosomes (i.e., X, Y, and Z), the unwrapped nucleosomes diffused slower than nucleosomes with $E > 0.25$. This is consistent with the predicted larger hydrodynamic radius of unwrapped nucleosomes as compared to the more compact fully wrapped nucleosomes, schematically depicted in the cartoons in Fig. 5, a–c (right panels). We note that nucleosomes that show FRET can still represent a heterogeneous population: although the FRET pair only reports on unwrapping at the side where it is located, X and Z feature symmetric unwrapping behavior. Therefore, in terms of hydrodynamic radius it can be expected that a fraction of nucleosomes is unwrapped on either side. How unwrapping of one end of the nucleosome affects the DNA at the other end remains an open question, however. Nucleosomes Y with $E > 0.25$ were anticipated to be partially unwrapped from the nucleosome end in 28% of the bursts, resulting in a more open structure and larger hydrodynamic radius, and therefore in slower diffusion than for completely wrapped end-labeled nucleosomes. The observed difference in diffusion time is comparable to the uncertainty, however, and better statistics are needed to confirm whether this difference is significant. Nucleosomes Y with $E < 0.25$ are unwrapped for at least
30-40 bp in 10% of the bursts ($K_{eq}$ ~0.1). Nucleosomes X and Z without FRET are unwrapped in 38% of the bursts ($K_{eq}$ ~0.6), and must therefore be either unwrapped for 10–20 bp (28%, $K_{eq}$ ~0.4) or for 30-40 bp (10%, $K_{eq}$ ~0.1). Surprisingly, this fraction showed the slowest diffusion of all fractions tested, even though the suggested conformation from the FRET signature does not correspond to the most unwrapped and extended state of the nucleosome. The differences in correlation times between nucleosome fractions can probably be more completely understood in the light of gel-retardation studies (25).

In conclusion, the combined PAGE-ALEX-spFRET-FCS data resolve an even more accessible set of conformations than obtained in solution.

DISCUSSION AND CONCLUSION

Combining PAGE, ALEX-spFRET, and FCS

To resolve the intrinsic dynamic heterogeneity of nucleosomes, it was necessary to combine PAGE-ALEX-spFRET and FCS in a single experiment. Each technique complements
in the work presented by Gansen et al. (10) and in our work, a fraction of ~10% free DNA is mentioned. Reconstitution reactions can be further purified with, for example, sucrose gradient ultracentrifugation (6,27), or PAGE with gel elution (28). This complicates sample preparation and does not necessarily result in a 100% pure nucleosome sample, as the conditions for purification may result in disassembly itself (28).

FCS analysis can be included with ALEX-spFRET spectroscopy and PAGE separation without any modifications of the experimental setup, since it only requires a correlation analysis of the detected photon streams to report on the diffusion behavior. Although photon selection criteria are common practice in FCS (e.g., based on the lifetime for time-gated FCS (29), or based on detection channel for a standard cross correlation), the correlation analysis on selected bursts presented here has not been reported before. By using bursts from a selected nucleosome population for FCS analysis, a diffusion time can be recovered that is directly related to the hydrodynamic radius of the population, which in turn depends on its conformation. Here we quantitatively compared correlation curves based on the $\tau_1$, avoiding fitting of the curves with an analytical expression. A model that describes the correlation curve would need to encompass 1), how the burst-selection algorithm affects the photon streams and how this influences the shape of the curve; 2), anomalous diffusion of nucleosomes in gel (22); and 3), an accurate description of DNA breathing conformational changes including its kinetics. A comprehensive analysis of these contributions is beyond the scope of this study, but could potentially uncover more details.

The application of this combined PAGE-ALEX-spFRET-FCS approach is not limited to the study of nucleosomes, but can, in principle, be exploited to study a variety of heterogeneous systems. Any process involving transient DNA-protein conformations, such as the action of ATP-dependent remodeling enzymes on nucleosomes, is dynamic and heterogeneous in nature. Only a single set of experiments is needed to extract a wealth of information about the conformational distribution and dynamics underlying such DNA-protein interactions.

**Progressive nucleosome unwrapping**

The combined data for end-labeled and internally labeled nucleosomes, both in free solution and in gel, indicate that transient DNA unwrapping occurs progressively from both nucleosome ends. This is consistent with the DNA breathing model, where transient DNA release initiates at the nucleosome end and proceeds inward (30). Progressive unwrapping from both ends implies that even in a homogeneous nucleosome population a variety of nucleosome conformations exists simultaneously. This was confirmed here based on diffusion times determined with FCS. Though the 601-DNA sequence used for nucleosome reconstitutions in this

![Graph](image_url)
work is not palindromic, we did not observe sequence-dependent DNA unwrapping from the nucleosome ends.

Our single-molecule observations of DNA breathing show much more pronounced unwrapping \( (K_{eq} \sim 0.1–0.6) \) than studies where DNA site exposure for different positions in the nucleosome was monitored using classical enzyme binding assays \( (K_{eq} = 0.02–0.1 \) at the nucleosome ends \( (6,8) \)). This difference may in part result from differences in experimental conditions and nucleosome constructs. In particular, at the subnucleosomal nucleosome concentrations used in this work, nucleosomes are known to be less stable because of weakened interactions with the H2A-H2B histone dimer that binds the region close to DNA ends \( (31) \), which is preceded by DNA breathing.

Unwrapping and rewrapping rates obtained by Li et al. \( (7) \) and by our previous work on immobilized nucleosomes \( (17,18) \) suggest that the lifetime of the unwrapped state is 10–50 ms. Fluctuations on this timescale cannot be resolved with our current approach, since the diffusion time is an order-of-magnitude smaller \( (\sim 1 \text{ ms}) \) than the predicted fluctuations. Fluctuations caused by nucleosome dynamics will affect the FRET value and the width of the distribution for different populations in an \( E \)-histogram. The latter information can be used to extract information about how the breathing rates compare to the diffusion time \( (32) \). For example, since the experiments in gel reveal a clear low FRET population of unwrapped nucleosomes in the histogram, we deduce that no conformational fluctuations that broaden this peak occurred during diffusion through the confocal volume. This yields a lower limit \( (\sim 4.5 \text{ ms in gel}) \) for the lifetime of the unwrapped state.

Disassembly of nucleosomes into substoichiometric histone-DNA complexes is increasingly recognized as a relevant process in chromatin structural maintenance \( (33) \). It vastly complicates the analysis of the nucleosome sample, because of the large number of possible conformations. Despite the pronounced DNA unwrapping far into the nucleosome, we did not observe irreversible nucleosome disassembly at low salt conditions or in the gel: the fraction of nucleosomes at low salt concentration in free solution experiments was the same as the fraction obtained from bulk experiments \( (\text{within experimental error}) \), and a sharp, stable band of nucleosomes in gel indicated that irreversible disassembly was absent. Nucleosome disassembly can be prevented by using high concentrations of unlabeled nucleosomes, as was demonstrated by Gansen et al. \( (10) \). This allowed us to perform experiments at physiological salt conditions in free solution \( (\text{data not shown}) \). In the experiments reported here, a gel matrix prevents dilution-driven nucleosome disassembly, possibly because of crowding. Crowded conditions may very well be physiologically relevant, since they closely resemble the situation in the cell nucleus.

In conclusion, our results show that the nucleosome is transiently unwrapped, but the histone proteins and the DNA remain stably associated. The nucleosome is more accessible to binding of regulatory proteins on the nucleosomal DNA than was shown previously \( (6) \). Our findings, obtained using a powerful combination of single-molecule fluorescence techniques and gel electrophoresis, emphasize the delicate interplay between DNA accessibility and condensation in chromatin. The method presented here is not restricted to the study of nucleosomes, but can be exploited to resolve the dynamics of other heterogeneous DNA-protein complexes as well.

SUPPLEMENTAL MATERIALS AND METHODS

Preparation of DNA and nucleosomes

Mononucleosomes were reconstituted on a fluorescently labeled 155 (bp) DNA template containing a 601 nucleosome positioning sequence as described (1). Briefly, the template DNA was prepared by PCR and was labeled with Cy3B (donor) and ATTO647N (acceptor) by incorporation of fluorescently labeled, HPLC purified primers (IBA GmbH, Göttingen, Germany). PCR primers were as follows (modified dT or dC underlined): Cy3B labeled forward primer: 5’-TT-GGCXGGAGAATCCCCGGTGCCCGAGGCCGCYCAATTGGTCGTAGACAGCTCTAGCA-C CGCTTTAACGCA CGZACCGCTG-3’; ATTO647N labeled reverse primer 5’-biotin-TT-GGAXZAGGATGTATATATCTGACACGTGCCTGGAGACTAGGGAGTAAYCCCCTTG-GCGGT TAAAACGXGGGGGACAGC-3’. We generated three DNA templates with this FRET pair (Förster radius \( R_0 \approx 5.5 \) nm) at either of the nucleosome extremes (labels at position X, or at position Z), and a position 27 basepair (bp) from one nucleosome end that we refer to as internally labeled in this work (labels at position Y), as shown in figure 1.a. In all DNA templates donor and acceptor were located ~80 bp (24 nm) apart. Nucleosomes were reconstituted by salt gradient dialysis with chicken erythrocyte histones as described (1). After reconstitution donor and acceptor were approximately 4 nm apart, resulting in efficient FRET, as confirmed by bulk fluorescence spectroscopy. Native gel electrophoresis, as described below, was used to determine the reconstitution yield, which were 70%, 90%, and 85% for reconstitutions X, Y, and Z respectively.

Sample preparation

Nucleosomes in free solution were diluted to a concentration of 100-200 pM in a buffer containing 10 mM Tris.HCl (pH 8), 0.1 mg/ml BSA, and 0.03 % NP-40. Reliable experiments could only be performed in the presence of 0.03% NP-40 anionic detergent, similar to the conditions established by Thåström et al. (2). If the NP-40 was omitted, no reproducible data could be taken and we observed a decrease in the number of bursts over time that we attributed to precipitation. For most experiments 2 mM Trolox (Sigma, Zwijndrecht, The Netherlands) was added to the buffer (3). A drop of 50 µl was placed on a glass cover slide (#1.5, Menzel, Braunschweig, Germany), and imaged as described below. Unless stated otherwise, experiments in this work were performed with nucleosomes labeled at position Y (see figure 1.a).

Nucleosomes in gel were imaged at single molecule concentration by excising the desired band from the gel. The gel slice was placed on a glass cover slide. A drop of 20 µl buffer was used to match the refractive of the gel and to prevent drying of the gel during the experiment.

Poly-acrylamide gel electrophoresis

Nucleosome reconstitutions were analyzed with 5% native poly-acrylamide gel electrophoresis (PAGE). A sample of 0.1-1 pmol was loaded on the gel (29:1 bis:acylamide, 0.2X TB).
SUPPLEMENTAL RESULTS

To characterize label stoichiometries and determine appropriate thresholds between different species, we used fluorescently labeled DNA samples that served as donor-only (D-only), acceptor-only (A-only), and doubly labeled species (D+A, no FRET). The corresponding 2D $E,S$-histograms revealed a single dominant population for each sample with the predicted $E,S$ signature (Figure S1.a-c. and Table S1). Considerable D-only and A-only species were present in the doubly labeled sample, effects of photobleaching. We used these results to determine the following thresholds for the experiments on nucleosomes: D-only: $S > 0.8$, and A-only: $S < 0.2$; free DNA and unwrapped nucleosomes without FRET: $E < 0.25$; wrapped nucleosomes with significant FRET: $E > 0.25$. Since the number of molecules with $E,S$-values close to the thresholds was small, the number of bursts in each fraction was only marginally dependent on the position of the threshold.
Table S1: $E, S$ signature of the dominant populations in Fig S1.a-c, and Fig 2.a.
